# Theoretical study of the $\mathrm{N}-\mathrm{H} \cdots \mathrm{O}$ red-shifted and blue-shifted hydrogen bonds 

#### Abstract

YANG Yong ${ }^{\dagger}$, ZHANG WeiJun, PEI ShiXin, SHAO Jie, HUANG Wei \& GAO XiaoMing Laboratory of Environmental Spectroscopy, Anhui Institute of Optics and Fine Mechanics, Chinese Academy of Sciences, Hefei 230031, China

Theoretical calculations are performed to study the nature of the hydrogen bonds in complexes $\mathrm{HCHO} \cdots \mathrm{HNO}, \mathrm{HCOOH} \cdots \mathrm{HNO}, \mathrm{HCHO} \cdots \mathrm{NH}_{3}, \mathrm{HCOOH} \cdots \mathrm{NH}_{3}, \mathrm{HCHO} \cdots \mathrm{NH}_{2} \mathrm{~F}$ and $\mathrm{HCOOH} \cdots \mathrm{NH}_{2} \mathrm{~F}$. The geometric structures and vibrational frequencies of these six complexes at the MP2/6-31+G(d,p), MP2/6-311++G(d,p), B3LYP/6-31+G(d,p) and B3LYP/6-311++G(d,p) levels are calculated by standard and counterpoise-corrected methods, respectively. The results indicate that in complexes HCHO $\cdots \mathrm{HNO}$ and $\mathrm{HCOOH} \cdots \mathrm{HNO}$ the $\mathrm{N}-\mathrm{H}$ bond is strongly contracted and $\mathrm{N}-\mathrm{H} \cdots \mathrm{O}$ blue-shifted hydrogen bonds are observed. While in complexes $\mathrm{HCHO} \cdots \mathrm{NH}_{3}, \mathrm{HCOOH} \cdots \mathrm{NH}_{3}, \mathrm{HCHO} \cdots \mathrm{NH}_{2} \mathrm{~F}$ and $\mathrm{HCOOH} \cdots \mathrm{NH}_{2} \mathrm{~F}$, the $\mathrm{N}-\mathrm{H}$ bond is elongated and $\mathrm{N}-\mathrm{H} \cdots \mathrm{O}$ red-shifted hydrogen bonds are found. From the natural bond orbital analysis it can be seen that the $X-H$ bond length in the $X-H \cdots Y$ hydrogen bond is controlled by a balance of four main factors in the opposite directions: hyperconjugation, electron density redistribution, rehybridization and structural reorganization. Among them hyperconjugation has the effect of elongating the $\mathrm{X}-\mathrm{H}$ bond, and the other three factors belong to the bond shortening effects. In complexes $\mathrm{HCHO} \cdots \mathrm{HNO}$ and $\mathrm{HCOOH} \cdots \mathrm{HNO}$, the shortening effects dominate which lead to the blue shift of the $\mathrm{N}-\mathrm{H}$ stretching frequencies. In complexes $\mathrm{HCHO} \cdots \mathrm{NH}_{3}, \mathrm{HCOOH} \cdots \mathrm{NH}_{3}, \mathrm{HCHO} \cdots \mathrm{NH}_{2} \mathrm{~F}$ and $\mathrm{HCOOH} \cdots \mathrm{NH}_{2} \mathrm{~F}$ where elongating effects are dominant, the $\mathrm{N}-\mathrm{H} \cdots \mathrm{O}$ hydrogen bonds are red-shifted.

red-shifted H-bond, blue-shifted H-bond, AIM topological analysis, NBO analysis

The deepening investigation on the nature of hydrogen bond is of importance since hydrogen bond is present in many chemical, physical and biological systems ${ }^{[1-3]}$. For this purpose quantum chemistry calculation is an effective way ${ }^{[4]}$. Blue-shifted hydrogen bond has attracted much attention since it was confirmed by theory and experiments ${ }^{[5-10]}$. Many plausible mechanisms have been proposed in interpreting this unusual phenomenon ${ }^{[11-17]}$. Hobza et al. ${ }^{[11]}$ proposed that there was difference in nature between blue-shifted and red-shifted hydrogen bonds. For the normal $\mathrm{X}-\mathrm{H} \cdots \mathrm{Y}$ red-shifted hydrogen bonds, electron transfers from the lone pair electron of electron donator to the $\sigma^{*}(\mathrm{X}-\mathrm{H})$ of the electron acceptor, which elongates the $\mathrm{X}-\mathrm{H}$ bond and leads to a red shift. For the blue-shifted hydrogen bonds, there
are two steps in the process. First, owning to hyperconjugation, the electron is transferred to the other parts of the electron acceptor, which elongates the other bonds of the acceptor. Second, the electron acceptor undergoes a structural reorganization which contributes to the $\mathrm{X}-\mathrm{H}$ contraction and blue shift of stretching frequency. Some other researchers considered that there was no difference between the blue-shifted and red-shifted hydrogen bonds in nature ${ }^{[13-17]}$. Alabugin et al. ${ }^{[16]}$ have recently shown that structural reorganization of $\mathrm{X}-\mathrm{H}$ bond in the process of both blue-shifted and red-shifted hydrogen bonds

[^0]is determined by the balance of the opposing effects: X - H bond elongating effect due to hyperconjugative $\mathrm{n}(\mathrm{Y})$ $\rightarrow \sigma^{*}(\mathrm{X}-\mathrm{H})$ interaction and $\mathrm{X}-\mathrm{H}$ bond shortening effect due to rehybridization. When the elongating effect plays the dominant role, there is red shift; otherwise, blue shift.

It should be noted that both theoretical and experimental researches on blue-shifted hydrogen bonds were mainly concentrated on the $\mathrm{C}-\mathrm{H}$ bond and very scarcely on the $\mathrm{N}-\mathrm{H}$ bond. Alabugin et al. ${ }^{[16]}$ predicted that the $\mathrm{N}-\mathrm{H} \cdots \mathrm{Y}$ blue-shifted hydrogen bond was possible if hyperconjugation was quite weak $\left(<13 \mathrm{~kJ} \cdot \mathrm{~mol}^{-1}\right)$. Both Hobza and Li et al. ${ }^{[15,18]}$ have predicted a blue-shifted $\mathrm{N}-\mathrm{H} \cdots \mathrm{F}$ H-bond existing in complex $\mathrm{NHF}_{2} \cdots \mathrm{HF}$ at the MP2/6-31G(d,p) and MP2/ $6-311+G(d, p)$, respectively. However, the blue shifts observed in their work are quite small, only 13 and 17 $\mathrm{cm}^{-1}$, respectively. In the present work, we have observed remarkable blue shifts $\left(>100 \mathrm{~cm}^{-1}\right)$ of the $\mathrm{N}-\mathrm{H}$ bond in the $\mathrm{HCHO} \cdots \mathrm{HNO}$ and $\mathrm{HCOOH} \cdots \mathrm{HNO}$ complexes where hyperconjugation is more than $21 \mathrm{~kJ} \cdot \mathrm{~mol}^{-1}$. It is in disagreement with the prediction proposed by Alabugin. In addition, the mechanism of $\mathrm{N}-\mathrm{H} \cdots \mathrm{O}$ blue-shifted and red-shifted hydrogen bonds in different complexes is discussed.

## 1 Computational methods

The structures and vibrational frequencies of the complexes were investigated using both standard and coun-terpoise-corrected ${ }^{[19,20]}$ (CP) optimization at the MP2/6-31+G(d,p), MP2/6-311++G(d,p), B3LYP/6-31+G $(d, p)$ and $B 3 L Y P / 6-311++G(d, p)$ levels, respectively. The basis set superposition errors (BSSE) were calculated according to the counterpoise method proposed by Boys and Bernardi ${ }^{[20]}$. The partial optimizations on the HNO monomer were performed at MP2/6-31+G(d,p) and MP2/6-311++G(d,p) levels. According to Onsager model, the SCRF calculations on the HNO monomers and complex B were carried out at B3LYP/ 6-31+G(d,p) level. Atoms in molecules (AIM) ${ }^{[21]}$ analysis were also carried out at the MP2/6-31+G(d,p) level. Natural bond orbital $(\mathrm{NBO})^{[22]}$ analysis was performed at the MP2/6-31+G(d,p) level. All the calculations are performed using the Gaussian 03 program packages.

## 2 Results and discussion

### 2.1 Geometries, frequencies and energies

All optimized complexes are described in Figure 1. The characteristics of the complexes determined by both standard and CP optimization procedures at MP2/ $6-31+G(d, p), M P 2 / 6-311++G(d, p), B 3 L Y P / 6-31+G(d, p)$ and B3LYP/6-311++G(d,p) levels are presented in Tables 1 and 2. As depicted in Figure 1, there is an N $\mathrm{H} \cdots \mathrm{O}$ hydrogen bond and an $\mathrm{X}-\mathrm{H} \cdots \mathrm{Y}(\mathrm{X}=\mathrm{O}$ and C ; $\mathrm{Y}=\mathrm{F}, \mathrm{N}$ and O ) hydrogen bond in all the complexes simultaneously, forming cyclic structures. For complexes A and B, the bond length (N2-H1) obtained by MP2 method agrees well with that obtained by B3LYP method. Similar results can also be found for the other complexes C, D, E and F. According to the basis sets effect, it can be seen that there is inconspicuous effect on the optimized structures. Owing to the existence of BSSE, the interaction energies are overestimated by the standard calculations ${ }^{[19]}$. In order to eliminate this effect, the CP-corrected calculations were performed. Compared to the standard calculations, the bond lengths obtained by CP-corrected calculations are obviously longer.

As shown in Table 2, the bond lengths (N1-H2 or $\mathrm{N} 1-\mathrm{H} 3$ ) in complexes $\mathrm{C}, \mathrm{D}, \mathrm{E}$ and F are longer than those in the monomers and corresponding stretching frequencies are lower, indicating the red-shifted N $\mathrm{H} \cdots \mathrm{O}$ hydrogen bonds. On the contrary, the bond lengths ( $\mathrm{N} 1-\mathrm{H} 2$ ) in complexes A and B contract relative to those in the monomers and corresponding stretching frequencies increase, which indicate that there are blue shifts. All calculations show the blue shifts are up to 144 $\mathrm{cm}^{-1}$ at most and up to $108 \mathrm{~cm}^{-1}$ at least. Although it has been predicted that a blue-shifted $\mathrm{N}-\mathrm{H} \cdots \mathrm{F}$ H-bond exists in the $\mathrm{NHF}_{2} \cdots \mathrm{HF}$ complex, the corresponding blue shift is only $13 \mathrm{~cm}^{-1}$ at MP2/6-311+G(d,p) level ${ }^{[15]}$.

The intermolecular interaction energies with both BSSE correction and ZPE correction are listed in Table 2. As shown in Table 2, the BSSE corrected and ZPE corrected energies are relatively large. The results indicate that BSSE correction and ZPE correction are important to accurately describe the intermolecular interaction energies. Among all complexes, complex $D$ is the most stable and complex C is the most unstable.

Figure 1 The optimized structure of the monomers and complexes.

### 2.2 AIM analysis

In order to shed light on the nature of the hydrogen bonds, the electron density topological analysis of the six complexes was performed at MP2/6-31+G(d,p) level. According to the AIM theory proposed by Bader ${ }^{[21]}$, the topological characteristics of electron density depend on the grads vector of electron density $(\nabla \rho(r))$ and Laplacian of electron density $\left(\nabla^{2} \rho(r)\right)$ values. Here, $\nabla^{2} \rho=$ $\lambda_{1}+\lambda_{2}+\lambda_{3}, \lambda_{i}$ 's is an eigenvalue of the Hessian matrix of $\rho$. Then, when one of the three $\lambda_{i}$ 's is positive and the other two are negative, we denote it by $(3,-1)$ and call it the bond critical point (BCP). When one of the three $\lambda_{i}$ 's is negative and the other two are positive, we denote it
by $(3,+1)$ and call it the ring critical point (RCP), which indicates the existence of a ring structure. $\rho$ is used to describe the strength of a bond and $\nabla^{2} \rho$ describes the characteristic of the bond. Usually, the larger the value of $\rho$ is, the stronger the bond is. Popelier et al. ${ }^{[23,24]}$ proposed eight criteria for judging the existence of hydrogen bonds, among which three were the most fundamental and often applied, as Lipkowski et al. ${ }^{[25]}$ pointed out. These three fundamental criteria are: the existence of a bond critical point, the electron density $(\rho)$ and its Laplacian $\left(\nabla^{2} \rho\right)$ values being in the range of $0.002-$ 0.034 and $0.02-0.14$ a.u., respectively.

and ring critical point at the MP2/6-31+G(d,p) level are listed in Table 3. The values of $\rho$ and $\nabla^{2} \rho$ for $\mathrm{O} 5 \cdots \mathrm{H} 1$ and $\mathrm{O} 3 \cdots \mathrm{H} 6$ in complexes A and $\mathrm{B}, \mathrm{O} 6 \cdots \mathrm{H} 2$ and $\mathrm{N} 1 \cdots \mathrm{H} 7$ in complexes C and $\mathrm{D}, \mathrm{O} 6 \cdots \mathrm{H} 3$ and $\mathrm{F} 2 \cdots \mathrm{H} 7$ in complexes E and F do fall within the proposed typical range of the hydrogen bonds. On the basis of the AIM topological analysis, we can claim that $\mathrm{N}-\mathrm{H} \cdots \mathrm{O}$ and X $-\mathrm{H} \cdots \mathrm{Y}(\mathrm{X}=\mathrm{O}$ and $\mathrm{C} ; \mathrm{Y}=\mathrm{F}, \mathrm{N}$ and O$)$ can be classified as hydrogen bonds. The strength of $\mathrm{N}-\mathrm{H} \cdots \mathrm{O}$ in complexes B, E and F is relatively strong, while those of $\mathrm{N}-\mathrm{H} \cdots \mathrm{O}$ in complexes C and D are relatively weak. These results are in good agreement with the $\mathrm{O} \cdots \mathrm{H}$ bond distances. In addition, there are RCPs in all the six complexes under investigation. A six-membered cyclic structure is observed for complexes $\mathrm{A}, \mathrm{D}$ and E , a
seven-membered cyclic structure can be seen in complexes B and F , and a five-membered cyclic structure appears for complex C .

### 2.3 NBO analysis

In order to investigate the mechanism on the blueshifted or red-shifted hydrogen bonds, the NBO analysis was performed at MP2/6-31+G(d,p) level and the corresponding results are listed in Table 4. In the NBO analysis, the importance of hyperconjugative interaction and electron density transfer (EDT) from lone electron pairs of the Y atom to the $\mathrm{X}-\mathrm{H}$ antibonding orbital in the $\mathrm{X}-\mathrm{H} \cdots \mathrm{Y}$ system is well known, which leads to an increase in population of $\mathrm{X}-\mathrm{H}$ antibonding orbital. The increase of electron density in $\mathrm{X}-\mathrm{H}$ antibonding orbital

weakens the $\mathrm{X}-\mathrm{H}$ bond, which leads to its elongation and concomitant red shift of $\mathrm{X}-\mathrm{H}$ stretching frequency. In general, the larger the hyperconjugative $\mathrm{n}(\mathrm{Y}) \rightarrow$ $\sigma^{*}(\mathrm{X}-\mathrm{H})$ interaction, the larger the electron density increase in the $\sigma^{*}(\mathrm{X}-\mathrm{H})$, and the $\mathrm{X}-\mathrm{H}$ bond length elongation becomes more obvious. From Table 4, the hyperconjugative $\mathrm{n}(\mathrm{O} 5) \rightarrow \sigma^{*}(\mathrm{~N} 2-\mathrm{H} 1)$ interaction in complex A is larger than the hyperconjugative $\mathrm{n}(\mathrm{O} 6) \rightarrow$ $\sigma^{*}(\mathrm{~N} 1-\mathrm{H} 2)$ interaction in complex C , however, the $\sigma^{*}(\mathrm{~N} 1-\mathrm{H} 2)$ electron density increase in complex A is obviously smaller than that in the $\sigma^{*}(\mathrm{~N} 1-\mathrm{H} 2)$ in complex C. Comparing the monomers $\mathrm{HNO}, \mathrm{NH}_{2} \mathrm{~F}$ and
$\mathrm{NH}_{3}$, we can see that for monomer HNO the hyperconjugative $\mathrm{n}_{2}(\mathrm{O} 3) \rightarrow \sigma^{*}(\mathrm{~N} 2-\mathrm{H} 1)$ interaction is up to 61.21 $\mathrm{kJ} \cdot \mathrm{mol}^{-1}$ and the electron density in the $\sigma^{*}(\mathrm{~N} 2-\mathrm{H} 1)$ is up to 0.02462 e . For the monomer $\mathrm{NH}_{2} \mathrm{~F}$, the hyperconjugative $\mathrm{n}(\mathrm{F} 2) \rightarrow \sigma^{*}(\mathrm{~N} 1-\mathrm{H} 3)$ interaction is relatively small and $\sigma^{*}(\mathrm{~N} 1-\mathrm{H} 3)$ electron density is 0.00492 e . However, for $\mathrm{NH}_{3}$, the electron density of $\sigma^{*}(\mathrm{~N} 1-\mathrm{H} 2)$ is 0.0 e . It should be remarked that the hyperconjugative $\mathrm{n}(\mathrm{O} 3) \rightarrow \sigma^{*}(\mathrm{~N} 2-\mathrm{H} 1)$ interactions in complexes A and B are obviously lower than those in the HNO monomers from Table 4 , which indicates a strong electron density redistribution in the electron acceptor HNO. Owing to

the electron density redistribution, in complexes A and B , electrons are transferred from $\mathrm{n}(\mathrm{O} 5)$ to $\sigma^{*}(\mathrm{~N} 2-\mathrm{H} 1)$ firstly, then most electrons in the $\sigma^{*}(\mathrm{~N} 2-\mathrm{H} 1)$ are transferred to $\mathrm{n}(\mathrm{O} 3)$, which greatly weakens $\mathrm{N} 2-\mathrm{H} 1$ bond length elongation. For complexes C and D , the electron is completely transferred to the $\sigma^{*}(\mathrm{~N} 1-\mathrm{H} 2)$ because there are no electron density redistribution effects. For complexes E and F , the electron density redistribution is relatively weak, therefore, most electrons are transferred to $\sigma^{*}(\mathrm{~N} 1-\mathrm{H} 3)$ and a small part of electrons are transferred to the $n(F 2)$. From the above analysis, it can be concluded that the electron density redistribution primarily depends on the characteristics of the monomers. Generally, the larger electron density in $\sigma^{*}(X-H)$ leads to the stronger electron density redistribution, as a consequence, the $\mathrm{X}-\mathrm{H}$ bond length elongation is more effectively inhibited. This well explains why in complexes A and B , the $\sigma^{*}(\mathrm{~N} 2-\mathrm{H} 1)$ electron density increase is relatively small although the hyperconjugative $\mathrm{n}(\mathrm{O} 5) \rightarrow$ $\sigma^{*}(\mathrm{~N} 2-\mathrm{H} 1)$ interaction is rather large.

Alabugin et al. ${ }^{[16]}$ have recently proposed that rehybridization is the main factor for the H -bond blue shifts. In their opinion, the positive charge of the H atom in the $\mathrm{X}-\mathrm{H} \cdot \cdots \mathrm{Y}$ hydrogen bonds is more than that in the monomer; according to Bent's rule, rehybridization increases the s-character of $\mathrm{X}-\mathrm{H}$ bond, strengthens its polarization, and consequently, shortens the $\mathrm{X}-\mathrm{H}$ bond. Seen from Table 4, our results coincide well with the
results of rehybridization. In all the complexes under investigation, the positive charges on the H atom of N 2 -H 1 (N1-H2 and N1-H3) increase, so do the s-character of the hybrid orbital in N2-H1 (N1-H2 and $\mathrm{N} 1-\mathrm{H} 3$ ) and the polarizations. The s-character in $\mathrm{N} 2-\mathrm{H} 1$ of complexes A and B is more noticeably increased than those of the other complexes owing to the lower s-characters and stronger rehybridization in HNO monomer than in $\mathrm{NH}_{3}$ and $\mathrm{NH}_{2} \mathrm{~F}$ monomers. This is in good agreement with the results through comparing $\mathrm{CH}_{4}$ with $\mathrm{C}_{2} \mathrm{H}_{2}$ by Alabugin et al. ${ }^{[16]}$.

### 2.4 Comparison to other theory

Hobza et al. ${ }^{[11]}$ proposed that there was difference in nature between the red-shifted and blue-shifted hydrogen bonds and the structural reorganization is the fundamental reason for the blue-shifted H -bond. As listed in Table 2, the bond lengths (N2-O3) in HNO and bond lengths (N1-F2) in $\mathrm{NH}_{2} \mathrm{~F}$ are evidently elongated in complexes A, B, E and F. N2-H1 $\cdots$ O 5 hydrogen bonds in complexes A and B are blue-shifted, while N1$\mathrm{H} 3 \cdots \mathrm{O} 6$ in complexes E and F are red-shifted, therefore, the structure reorganization should not be the natural difference between the red-shifted and blue-shifted hydrogen bonds. In order to deepen the understanding of the structural reorganization effect on the blue shift of N - H bond, the partial optimization on the HNO monomer was performed at MP2/6-31+G(d,p) and MP2/ $6-311++G(d, p)$ levels. In this process, we optimized the

HNO monomer with an elongated $\mathrm{N}-\mathrm{O}$ bond taken from the optimized complex A and B, and this bond was kept frozen during the optimization. The results in Table 5 show that $\mathrm{N} 2-\mathrm{O} 3$ bond elongation can only lead to a small contraction in bond length and a slight blue shift in stretching frequencies of $\mathrm{N} 2-\mathrm{H} 1$. For complexes A and B, at the MP2/6-31+G(d,p) level the blue shifts are up to 112 and $115 \mathrm{~cm}^{-1}$, while they are only 15 and 16 $\mathrm{cm}^{-1}$ due to the structural reorganizations. Therefore, we can exclude the possibility of the structural reorganiza-
tion being the fundamental reason for the blue-shifted hydrogen bond.

Alabugin et al. ${ }^{[16]}$ proposed that the blue-shifted and red-shifted hydrogen bonds were determined by the balance of the opposing effects: $\mathrm{X}-\mathrm{H}$ bond elongating effect due to hyperconjugative $\mathrm{n}(\mathrm{Y}) \rightarrow \sigma^{*}(\mathrm{X}-\mathrm{H})$ interaction and $\mathrm{X}-\mathrm{H}$ bond shortening effect due to rehybridization. When $\mathrm{X}-\mathrm{H}$ bond elongating effect is dominant, the $\mathrm{X}-\mathrm{H}$ bond elongates. When $\mathrm{X}-\mathrm{H}$ bond shortening effect is dominant, the $\mathrm{X}-\mathrm{H}$ bond shortens. Further-

Table 5 The change between the partial optimized HNO and all optimized HNO of the bond lengths ( $\mathrm{N} 2-\mathrm{H} 1$ ) and stretching frequencies at MP2/6-31+G(d,p) and MP2/6-311++G(d,p) levels

more, Alabugin et al. suggested that red shift and blue shift are determined by the threshold which corresponds to the hyperconjugative $\mathrm{n}(\mathrm{Y}) \rightarrow \sigma^{*}(\mathrm{X}-\mathrm{H})$ interaction in the order of $13-21 \mathrm{~kJ} \cdot \mathrm{~mol}^{-1[16]}$. The red-shifted hydrogen bond is observed when the $\mathrm{X}-\mathrm{H}$ bond elongating hyperconjugative $n(Y) \rightarrow \sigma^{*}(X-H)$ interaction is relatively strong ( $>21 \mathrm{~kJ} \cdot \mathrm{~mol}^{-1}$ ). The blue-shifted H-bond is likely to be observed only when the $\mathrm{X}-\mathrm{H}$ bond elongating hyperconjugative $n(Y) \rightarrow \sigma^{*}(X-H)$ interaction is relatively weak $\left(<13 \mathrm{~kJ} \cdot \mathrm{~mol}^{-1}\right)$. However, our calculation shows that there are obviously blue-shifted $(>100$ $\mathrm{cm}^{-1}$ ) $\mathrm{N} 2-\mathrm{H} 1 \cdots \mathrm{O} 5$ hydrogen bonds in complexes A and $B$ in spite of the strong hyperconjugative $n(O 5) \rightarrow$ $\sigma^{*}(\mathrm{~N} 2-\mathrm{H} 1)$ interaction $\left(>21 \mathrm{~kJ} \cdot \mathrm{~mol}^{-1}\right)$. The model proposed by Alabugin could not provide a reasonable explanation on this result. Besides the strong hyperconjugation in complexes A and B , we also notice the prominent electron density redistribution for the electron acceptor HNO, which can restrain the $\mathrm{N} 2-\mathrm{H} 1$ elongation. On the other hand, the more the hyperconjugation is, the stronger the rehybridization effect is. As a result, the increase in the s-character of spn hybrid orbital for the N2-H1 bond leads to intense contraction of the N2H 1 bond in complexes A and B. Consequently, the origins of blue-shifted H -bonds can be more clearly interpreted by our model.

On the basis of the above analyses, there are four factors affecting the red-shifted or blue-shifted hydrogen bonds: hyperconjugation, electron density redistribution, rehybridization and structural reorganization. Hyperconjugation contributes to the bond elongating effect, and the other three effects contribute to the bond shortening effect. It is worth pointing out that electron density redistribution and rehybridization are related to the character of the monomers. In general, the larger the electron density in $\sigma^{*}(X-H)$, the stronger the electron density redistribution. The lower the s-character of spn hybrid orbital for the $\mathrm{X}-\mathrm{H}$ bond, the stronger the rehybridization. On the other hand, with the hyperconjuga-
tion increasing, the bond elongating effect increases, so do the electron density redistribution and rehybridization. All these four effects contribute to the N2-H1(N1-H3) bond length changes in complexes $\mathrm{A}, \mathrm{B}, \mathrm{E}$ and F . The hydrogen bonds $\mathrm{N} 2-\mathrm{H} 1 \cdots \mathrm{O} 5$ in the complexes A and B are blue-shifted, while $\mathrm{N} 1-\mathrm{H} 3 \cdots \mathrm{O} 6$ in complexes E and F are red-shifted. Therefore, we completely agree with those who conclude that there are no fundamental differences between the red-shifted or blue-shifted hydrogen bonds. Among all six complexes, the electron density in $\sigma^{*}(\mathrm{~N}-\mathrm{H})$ for HNO is the largest and the s-character of spn hybrid orbital for the $\mathrm{N}-\mathrm{H}$ bond is lowest, so the $\mathrm{N}-\mathrm{H}$ bond shortening effect is dominant, which leads to a large blue shift of stretching frequency. On the contrary, in complexes C, D, E and F, the elongating effects dominate resulting in red-shifted H -bonds.

### 2.5 Solvent effect on the structures, frequencies and interaction energies

In order to investigate the solvent effect on the structures, frequencies and interaction energies of monomers and complexes, the SCRF calculations were performed on the monomers and complexes at B3LYP/6-31+G(d,p) level (the relatively dielectric constants are $2.23,8.93$, $24.55,32.63,36.64$ and 78.39 , respectively). The corresponding results are summarized in Table 6. It is clear from the change of bond lengths given in Table 6 that solvent effect leads to decrease of the N2-H1 bond length in the HNO monomer. This behavior is more evident as $\varepsilon$ is below 10.0 . For complex B , the solvent effect on the structure is not significant. With the increase of $\varepsilon$, the $\mathrm{O} 5-\mathrm{H} 1$ bond length shows a slight contraction while the $\mathrm{O} 3-\mathrm{H} 6$ bond length has a small elongation. The $\mathrm{N} 2-\mathrm{H} 1$ bond length is almost independent of $\varepsilon$. As shown in Table 6, the solvent effects have a different influence on the geometries of complex B and the monomer HNO. As a result, the blue shift of the $\mathrm{N} 2-\mathrm{H} 1$ stretching frequency decreases as $\varepsilon$ increases. At the B3LYP/6-31+G(d,p) level, the N2-H1

Table 6 The partial optimized parameters of HNO monomer and complex B in different solvents at B3LYP/6-31+G(d,p) levels
