**Abstract.** Synthesis of atomically dispersed catalysts with high metal loading and thermal stability is challenging but particularly valuable for industrial applications in heterogeneous catalysis. Here, we report a facile synthesis of a thermally stable atomically dispersed Ir/ $\alpha$ -MoC catalyst with metal loading as high as 4 wt%, an unusually high value for carbide supported metal catalysts. The strong interaction between Ir and the  $\alpha$ -MoC substrate enables high dispersion of Ir on the  $\alpha$ -MoC surface, and modulates the electronic structure of the supported Ir species. Using quinoline hydrogenation as a model reaction, we demonstrate that this atomically dispersed Ir/ $\alpha$ -MoC catalyst exhibits remarkable reactivity, selectivity, and stability, for which the presence of high-density isolated Ir atoms is the key to achieve high metal-normalized activity and mass-specific activity. We also show that water-promoted quinoline hydrogenation mechanism is preferred over the Ir/ $\alpha$ -MoC, which contributes to high selectivity towards

1,2,3,4-tetrahydroquinoline. The present work demonstrates a new strategy to construct high-loading atomically dispersed catalyst towards hydrogenation reaction.

**Key words:** Atomically dispersed catalysts, high metal loading, molybdenum carbide, hydrogenation of quinoline

## INTRODUCTION

Atomically dispersed catalysts have received extensive research attention,(1-8) because they exhibit excellent activity and unique selectivity for many important catalytic reactions, such as CO oxidation,(9-11) water gas shift reaction(12-14) and hydrogenation of organic compounds.(15-20) The atomically dispersed nature of these metal catalysts confers their unique electronic structures as well as designated coordination-unsaturated environments for the optimized adsorption/activation of the reactants. One grand challenge faced by these atomically dispersed catalysts is that the supported metal single-atoms are usually thermally unstable and tend to aggregate into large clusters/particles at evaluated reaction temperatures.(21) Furthermore, most reported atomically dispersed catalysts have an extremely low metal loading below 1.5wt%.(22) Because of the extremely low metal loading, many atomically dispersed catalysts suffer from low mass-specific activity, which is often considered more crucial, especially in industrial applications. Therefore, developing new strategies for constructing atomically dispersed catalysts with high metal loading, high thermal stability, and high catalytic performance is of great importance.

In order to achieve high metal loading and high thermal stability, the support material should have a high specific surface area with abundant surface sites that could provide strong anchoring to the supported metal species. Meanwhile, for optimizing the catalytic performance, the support material should also be carefully chosen to tune the electronic properties of the supported species, and to participate in catalyzing the reaction.(23, 24) For example, in atomically dispersed Pt/ $\alpha$ -MoC catalyst, the  $\alpha$ -MoC support not only endows the accommodated Pt species with the atomically dispersed nature, but also facilitates the splitting of water and the generation of hydrogen and reactive surface hydroxyl groups, which is critical for the aqueous reforming of methanol into hydrogen and CO<sub>2</sub>. Constructing atomically dispersed catalysts using active substrates, such as transition metal carbides and nitrides, is, therefore, crucial in catalyst design. (25-28)

Herein, we reported the synthesis of an atomically dispersed Ir catalyst on active  $\alpha$ -MoC support with 4 wt% Ir loading through a facile wet-impregnation method. Additionally, the high-loading atomically dispersed Ir/ $\alpha$ -MoC catalyst can efficiently catalyze the hydrogenation reaction of quinoline towards 1,2,3,4-Tetrahydroquinoline (py-THQ), an important building block in pharmaceuticals and fine chemicals.(29-46) We observed that the  $\alpha$ -MoC

host endorsed the catalyst unexpected capability to block the unselective hydrogenation of benzene ring of quinoline without sacrificing the catalytic activity under our reaction condition. The origin of the high reactivity and especially the high selectivity of the current catalyst construct, as compared with pure Ir metal catalysts, is further explained by the first-principles microkinetic simulations.

## RESULTS AND DISCUSSIONS

### Structure analysis of Ir/ $\alpha$ -MoC

x% Ir/ $\alpha$ -MoC (x, ranging from 0.5 to 12, is the approximate Ir loading in wt%) samples were synthesized through a facile wet-impregnation method under Ar protection, followed by carburization in CH<sub>4</sub>/H<sub>2</sub> flow at 590 °C (Figure 1A). X-ray diffraction (XRD) patterns of the 0.5% Ir/ $\alpha$ -MoC, 4% Ir/ $\alpha$ -MoC and 7% Ir/ $\alpha$ -MoC catalysts (Figure 1B) match well with the standard pattern of  $\alpha$ -MoC.<sup>(23)</sup> The absence of diffractions associated with Ir crystal indicates that the size of Ir species in these samples is below the detection limit of XRD. However, when we increase the Ir loading to 12%, besides the peaks assigned to  $\alpha$ -MoC, new peaks associated with metallic Ir crystal appear,<sup>(47)</sup> which implies that Ir aggregates into larger nanoparticles (NPs) in 12% Ir/ $\alpha$ -MoC catalyst.

The structure of  $\alpha$ -MoC supported Ir species was further investigated using X-ray absorption fine structure (XAFS) characterizations. The Ir L<sub>3</sub>-edge XAFS (Figure 1C) shows that the near-edge absorption energy of Ir on  $\alpha$ -MoC is located between those of Ir foil and IrO<sub>2</sub>, suggesting that the Ir species are partially positively charged in these Ir/ $\alpha$ -MoC catalysts, which demonstrates the strong interaction between  $\alpha$ -MoC and supported Ir species. The extended X-ray absorption fine structure (EXAFS, Figure 1D) spectra and the corresponding fitting results (Figure S1 and Table S1) show the absence of Ir-Ir scattering in the 4% Ir/ $\alpha$ -MoC, indicating full atomic dispersion of Ir over  $\alpha$ -MoC. The coordination number of Ir-Mo and Ir-C shell is 7.3 and 1.4 for 4% Ir/ $\alpha$ -MoC, respectively. The high Ir-Mo and Ir-C coordination numbers imply that Ir atoms are embedded in the Mo-terminated  $\alpha$ -MoC surface, enabling excellent thermal stability. The coordination number of Ir-Ir (CN<sub>Ir-Ir</sub>) increases to 2.6 for 7% Ir/ $\alpha$ -MoC, indicating that small Ir clusters start to form at this Ir loading. For 12% Ir/ $\alpha$ -MoC, CN<sub>Ir-Ir</sub> further increases to 4.2 with the formation of XRD-detectable Ir NPs.

To further unravel the structure of the Ir/ $\alpha$ -MoC catalysts, aberration-corrected scanning transmission electron microscopy (STEM) analysis was performed. As shown by the typical STEM image of 4% Ir/ $\alpha$ -MoC sample (Figure 2A), the  $\alpha$ -MoC support, with an average grain size of ~5 nm, preserves as a porous matrix even after Ir loading. Some isolated atomic sites with high contrast (highlighted in red circles, marked as Ir<sub>1</sub>) can be clearly

distinguished in the STEM annular dark field (ADF) images (Figure 2B), which can be identified as Ir<sub>1</sub> atoms supported on  $\alpha$ -MoC (Figure S2). When the Ir loading is increased to 7%, the surface density of the Ir<sub>1</sub> atoms also increases considerably (Figure 2C), and no severe Ir segregation was observed in the corresponding energy-dispersive X-ray spectroscopy (EDS) mapping (Figure S3B). High resolution electron energy loss spectroscopy (EELS) mapping result (Figure S3E), however, reveals the formation of very small Ir clusters (masked with the dashed yellow circles in Figure 2C and S3D) in the 7% Ir/ $\alpha$ -MoC sample, which is consistent with the EXAFS fitting results. Notably, despite the emergence of Ir clusters, the 7% Ir/ $\alpha$ -MoC still has a higher Ir<sub>1</sub> density than that of the 4% Ir/ $\alpha$ -MoC (Figure S4). Even for the 12% Ir/ $\alpha$ -MoC sample, a considerable density of isolated Ir<sub>1</sub> atoms are still observed (Figure 2D), with the coexistence of Ir clusters and NPs as revealed by STEM-EDS and STEM-EELS mappings (Figure S5 and S6). Density functional theory (DFT) calculations reveal that the formation of Ir<sub>1</sub>/ $\alpha$ -MoC is slightly endothermic by 0.36 eV with respect to the defective  $\alpha$ -MoC (111) surface and an Ir atom in bulk, demonstrating the high possibility in the formation of atomically dispersed Ir/ $\alpha$ -MoC catalyst. The DFT results are in excellent agreement with our experimental observation that an ultra-high density of atomically dispersed Ir dominates on  $\alpha$ -MoC support even at a high Ir loading of 7 %.

#### **Catalytic performance of Ir/ $\alpha$ -MoC towards quinoline hydrogenation.**

We evaluated Ir/ $\alpha$ -MoC catalysts for the hydrogenation reaction of quinoline towards py-THQ at 120 °C and 3 MPa (reaction time: 1 hour). Over-hydrogenation of py-THQ will produce low value DHQ, especially under relatively high temperature and long reaction time. As seen from Table 1, bare  $\alpha$ -MoC exhibits poor activity (entry 1), whereas the activity for quinoline hydrogenation is significantly enhanced after the introduction of 0.5% of Ir (entry 2, 16% conversion). Conversion of quinoline dramatically increases to 85% when the Ir loading is increased to 4% (entry 3), which strongly suggests that the activation of quinoline occurs over the Ir motif. Significantly, the selectivity is unchanged, *i.e.* there is no formation of DHQ even at this high conversion of quinoline. When the Ir loading is further increased to 7%, a near unity conversion is reached but again no DHQ is detected (entry 4). To our surprise, when the Ir loading is 12%, while the selectivity remains unchanged, the conversion drops to 77% (entry 5).

To further understand the catalytic performance of the Ir/ $\alpha$ -MoC catalysts with different loading of Ir, we plot the metal-normalized activity and mass-specific activity of a series of Ir/ $\alpha$ -MoC catalysts at 20% conversion of quinoline as a function of Ir loading (Figure 3A, Table S2). While the metal-normalized activity indicates the

intrinsic activity of the catalytically active sites, the mass-specific activity represents the total power to convert the reactant over a catalyst with given mass, which is sometimes more important for industrial applications. When the Ir content is lower than 4%, where atomically dispersed Ir<sub>1</sub> dominates on  $\alpha$ -MoC surface, a constant metal-normalized activity (85-91 h<sup>-1</sup>) is observed, suggesting that the atomically dispersed Ir<sub>1</sub> species has a similar intrinsic activity. As shown in Figure 3A (right column), the mass-specific activity increases almost linearly with Ir content from 0.46  $\mu\text{mol}_Q \text{ g}^{-1} \text{ s}^{-1}$  (0.5% Ir/ $\alpha$ -MoC; Q refers to quinoline) to 4.9  $\mu\text{mol}_Q \text{ g}^{-1} \text{ s}^{-1}$  (4% Ir/ $\alpha$ -MoC). This further demonstrates that the atomically dispersed Ir<sub>1</sub> species has almost the same intrinsic reactivity, and increasing the density of Ir<sub>1</sub> species leads to the linearly increase in mass-specific activity.

Further increasing the loading of Ir, a different scenario was observed. When the loading of Ir increased to 7%, the metal-normalized activity decreased to 65 h<sup>-1</sup>. As shown in Figures 1 and 2, for the 7% Ir/ $\alpha$ -MoC catalyst, Ir clusters begin to appear, alongside with the Ir<sub>1</sub> species. The accompanied decrease in metal-normalized activity with the emergence of Ir clusters indicates that Ir<sub>1</sub> is more effective in the reaction than the aggregated Ir species. However, the mass-specific activity of 7% Ir/ $\alpha$ -MoC (6.5  $\mu\text{mol}_Q \text{ g}^{-1} \text{ s}^{-1}$ ) is still higher than that of 4% Ir/ $\alpha$ -MoC due to the higher Ir<sub>1</sub> density of the 7% Ir/ $\alpha$ -MoC catalyst (Figure S4), which again signals the importance of the presence of high density Ir<sub>1</sub> species for the reaction. When the loading of Ir increases to 12%, a sharp decrease of metal-normalized activity (23 h<sup>-1</sup>) is found, which is attributed to the aggregation of Ir<sub>1</sub> to Ir NPs, leading to the decrease in Ir<sub>1</sub> density. As a result, the mass-specific activity decreases to 4.3  $\mu\text{mol}_Q \text{ g}^{-1} \text{ s}^{-1}$ . This explains also the drop in conversion in Table 1 when the Ir loading reaches 12%. This observation demonstrates that increasing the loading of noble metal cannot always ensure a higher total power for the conversion of the reactants while an optimized dispersion/surface conformation is critical for the efficient utilization of noble metal resources.

Based on the results above, we can draw the conclusion that the Ir<sub>1</sub> species on  $\alpha$ -MoC surface are more reactive than Ir clusters or Ir NPs in this reaction, giving the highest metal-normalized activity on 0.5-4% Ir/ $\alpha$ -MoC catalysts. We need to point out that very low metal loading of a supported metal catalyst can result in an extremely low mass-specific activity, which is a drawback in practical applications. In our view, high-loading atomically dispersed catalyst (e.g. 4% Ir/ $\alpha$ -MoC) and catalyst with the highest density of isolated metal atom (e.g. 7% Ir/ $\alpha$ -MoC) are significant for both academia and chemical industry.

The selectivity towards py-THQ is another critical standard for quinoline hydrogenation catalyst, so we studied the time dependent reaction behavior of the 7% Ir/ $\alpha$ -MoC catalyst (Figure 3B). Significantly, 7% Ir/ $\alpha$ -MoC

catalyst achieves the yield of py-THQ at 94% with >99% selectivity in 1 hr. Prolonging the reaction time to 40 hrs, the selectivity remains unchanged, which suggests that the hydrogenation of benzene ring in quinoline is effectively blocked. For comparison, Ir catalyst supported over active carbon (7 % Ir/C catalyst) shows a high selectivity of 94% towards py-THQ at 1 hr (entry 6 in Table 1), but the selectivity towards the undesired DHQ gradually increases with reaction time and reaches 37% after 40 hrs. The different selectivity could be due to either the difference in Ir dispersion or the presence of the  $\alpha$ -MoC support. Different from 7% Ir/ $\alpha$ -MoC, 7% Ir/C catalyst is dominated with 2-3 nm Ir NPs (see Figure S7). However, as shown in Figure 3C, formation of undesired DHP was not detected in the 40 hrs hydrogenation reaction for 12% Ir/ $\alpha$ -MoC catalyst with the presence of Ir NPs. This strongly indicates that the  $\alpha$ -MoC substrate plays the dominant role for switching off the hydrogenation of benzene ring of quinoline, which cannot be realized by using conventional support like carbon black and SiO<sub>2</sub> (Figure 3C). Moreover, 7% Ir/ $\alpha$ -MoC shows remarkable stability with both conversion and selectivity maintaining after 5 cycles (Figure S8). The catalytic activity and stability of the 7% Ir/ $\alpha$ -MoC catalyst is comparable to the traditional supported nanoparticles (Table S3). (29-32, 48-50) As tested by ICP-AES, no Ir species was detected in the filter liquor, and Ir content in 7% Ir/ $\alpha$ -MoC catalyst did not change after 5 cycles. XRD and STEM analysis (Figure S9 and S10) confirm the good structural stability of Ir<sub>1</sub> under reaction conditions.

The 7% Ir/ $\alpha$ -MoC catalyst was further employed to catalyze the hydrogenation of quinoline derivatives with different functional groups. Only the hydrogenation of heteroarene ring was observed in the hydrogenation of quinoline derivatives (Table S4), while the hydrogenation of benzene ring of the quinoline derivatives was switched off effectively. Quinoline compounds bearing a methyl group at the 2- and 6- position could be completely hydrogenated to the corresponding py-THQ (Table S4, entries 2-3). Notably, the 7% Ir/ $\alpha$ -MoC catalyst could catalyze the hydrogenation of 8-hydroxyquinoline to biologically active 1,2,3,4-tetrahydro-8-hydroxyquinoline without any dehydroxylation (Table S4, entry 4). In a more challenging reaction, 6-chloroquinoline was reduced to the 6-chloro-1,2,3,4-tetrahydroquinoline with a conversion of 92% and a selectivity of 97% (Table S4, entry 5). Besides quinoline hydrogenation, the 7% Ir/ $\alpha$ -MoC catalyst also gives an extraordinary catalytic performance for the hydrogenation of isoquinoline (Table S4, entry 6).

### First-principles microkinetic simulations on quinoline hydrogenation

To understand the excellent reactivity and selectivity of Ir/ $\alpha$ -MoC catalyst in the hydrogenation reaction of quinoline, van der Waals (vdW) corrected DFT calculations combined with microkinetic simulations were

performed to study quinoline hydrogenation mechanisms over a series of catalysts. Ir(111),  $\alpha$ -MoC(111) and Ir<sub>1</sub>/ $\alpha$ -MoC(111) models were used to represent Ir particle catalyst,  $\alpha$ -MoC catalyst, and atomically dispersed Ir/ $\alpha$ -MoC catalyst, respectively. In order to exploring the solvent effect, a water molecule was considered in the present work to study the effect of water-mediated reaction route. Therefore, two quinoline hydrogenation mechanisms, namely direct and water-mediated quinoline hydrogenation pathways, were investigated. The calculated potential energy diagrams for quinoline hydrogenation towards py-THQ are presented in Figure 4. As compared with Ir, quinoline and py-THQ adsorb stronger on  $\alpha$ -MoC by 2.38 eV and 1.81 eV, respectively (Table S5), which can be attributed to a higher degree of charge transfer from metallic-like  $\alpha$ -MoC to quinoline/py-THQ enhancing the electrostatic interaction between  $\alpha$ -MoC and quinoline/py-THQ (Table S8). In analogy to quinoline/py-THQ adsorption,  $\alpha$ -MoC also binds the alternative reactants, namely H atom and H<sub>2</sub>O molecule, stronger than Ir by at least 0.45 eV (Table S5-S7). The presence of Ir<sub>1</sub> atom on  $\alpha$ -MoC surface further enhances quinoline adsorption while weakens py-THQ and hydrogen adsorption strengths slightly. The significantly different energetics for the adsorption of reactants and products over Ir,  $\alpha$ -MoC and Ir<sub>1</sub>/ $\alpha$ -MoC will result in distinct catalytic performances among them as described below.

We first studied the direct quinoline hydrogenation mechanism that all the intermediates are hydrogenated by the surface adsorbed hydrogen atoms (Figure 4A and Figure S11). All the direct quinoline hydrogenation steps are almost neutral on Ir with moderate hydrogenation barriers ranging from 0.67 eV to 1.01 eV. C<sub>9</sub>H<sub>8</sub>N hydrogenation step has the highest reaction barrier on Ir. In contrast, direct quinoline hydrogenation becomes highly endothermic over  $\alpha$ -MoC, with significantly high activation barriers ranging from 1.49 eV to 2.24 eV. Relatively lower hydrogenation reaction barriers of 1.18 eV to 1.62 eV were found on Ir<sub>1</sub>/ $\alpha$ -MoC. The higher activation barriers for direct quinoline hydrogenation on  $\alpha$ -MoC and Ir<sub>1</sub>/ $\alpha$ -MoC than on Ir metal cannot rationalize the experimental finding that Ir<sub>1</sub>/ $\alpha$ -MoC displays comparable activity to Ir.

In contrast to the direct hydrogenation mechanism, hydrogenation of quinoline via water-mediate becomes endothermic step-by-step on Ir (Figure 4B) due to the weak adsorption of OH intermediate ( $E_{\text{OH}} = -2.82$  eV). On Ir, the highest activation barrier in the water-mediate hydrogenation mechanism becomes 1.88 eV, which is 0.87 eV higher than that in the direct hydrogenation mechanism. Therefore, direct hydrogenation of quinoline is more favorable than water-mediated hydrogenation pathway over Ir. However, in contrary to Ir, quinoline hydrogenation via water-mediate is exothermic continuously on both  $\alpha$ -MoC and Ir<sub>1</sub>/ $\alpha$ -MoC structures (Figure 4B). Consequently,

the activation barriers for water-mediated hydrogenation mechanism become significantly lower than those in the direct hydrogenation route. In other words, water-mediated quinoline hydrogenation mechanism is more favorable than the direct hydrogenation route on both  $\alpha$ -MoC and  $\text{Ir}_1/\alpha$ -MoC catalysts.  $\text{Ir}_1/\alpha$ -MoC has lower hydrogenation barriers than  $\alpha$ -MoC because of their different transition state configurations in water-mediated quinoline hydrogenation mechanism. On  $\alpha$ -MoC, water molecule serves as a whole species to react with quinoline and the corresponding intermediates (Figure 4B and Figure S12). However, on  $\text{Ir}_1/\alpha$ -MoC, the detached H atom from water reacts with quinoline and  $\text{C}_9\text{H}_8\text{N}$  directly with the counterpart OH species moving away to Mo sites (Figure S13), which lowers the activation barriers for quinoline hydrogenation. Importantly, the activation barriers for each water-mediated quinoline hydrogenation step over  $\text{Ir}_1/\alpha$ -MoC are at least 0.40 eV lower than those in the direct hydrogenation mechanism on Ir metal.

To quantify the catalytic performance of Ir,  $\alpha$ -MoC and  $\text{Ir}_1/\alpha$ -MoC catalysts, microkinetic simulations were performed. The theoretically predicted activity trend for quinoline hydrogenation, *i.e.*  $\text{Ir} \sim \text{Ir}_1/\alpha\text{-MoC} > \alpha\text{-MoC}$ , is corroborated by our experimental measurements (Figure 5A). By possessing moderate hydrogenation activation barriers and surface coverage of H, Ir catalyst has an extraordinary activity for quinoline hydrogenation and direct hydrogenation of  $\text{C}_9\text{H}_8\text{N}$  is the rate-determining step (RDS) (Figure S14).  $\alpha$ -MoC has the lowest reaction rate and the water-mediated hydrogenation of quinoline ( $\text{C}_9\text{H}_7\text{N}$ ) is the RDS.  $\text{H}_2\text{O}$  dissociation is highly exothermic on  $\alpha$ -MoC. Therefore,  $\text{H}_2\text{O}$  dissociation is much feasible on  $\alpha$ -MoC and the  $\alpha$ -MoC surface is fully covered by OH/H species, leaving less active sites for the adsorption of quinoline. The high activation barrier of  $\text{C}_9\text{H}_7\text{N}$  hydrogenation and low surface coverage of  $\text{C}_9\text{H}_7\text{N}$  (Figure S14) both result in a significantly low activity of quinoline hydrogenation of  $\alpha$ -MoC. Additionally, quinoline hydrogenation activity is low on  $\text{Ir}_1/\alpha$ -MoC catalyst at relatively low temperatures. However, the reaction rate increases drastically at a higher temperature (from 120 - 180 °C), where  $\text{C}_9\text{H}_8\text{N}$  hydrogenation via water-mediate is identified as the RDS.  $\text{Ir}_1/\alpha$ -MoC has comparable quinoline hydrogenation activity to Ir catalyst at temperatures above 180 °C but with a different quinoline hydrogenation mechanism.

The water effect in quinoline hydrogenation was investigated by combining water with different kinds of neat solvents. The metal-normalized activity over the 7%  $\text{Ir}/\alpha$ -MoC catalyst using methanol/water, ethanol/water and N,N-dimethylformamide (DMF)/water as solvent is 65, 72 and  $7.7 \text{ h}^{-1}$ , respectively, all higher than that using neat methanol ( $33 \text{ h}^{-1}$ ), ethanol ( $53 \text{ h}^{-1}$ ) or DMF ( $3.6 \text{ h}^{-1}$ ) solvent (Figure S15). This strongly indicates that water promotes the hydrogenation of quinoline over the  $\text{Ir}/\alpha$ -MoC catalysts. In contrast, the addition of water into

methanol doesn't improve the metal-normalized activity of the 7% Ir/C catalyst. These results suggest that direct quinoline hydrogenation is more preferable on Ir/C catalyst while water plays an import role in quinoline hydrogenation over the Ir/ $\alpha$ -MoC catalyst, which are corroborated with our theoretical calculations.

The unexpected good selectivity of quinoline hydrogenation over the Ir/ $\alpha$ -MoC catalyst is evaluated by the comparing the competition between py-THQ desorption and further hydrogenation. On Ir, the calculated hydrogenation barrier and desorption energy of py-THQ are 0.82 and 0.40 eV per site, respectively (Figure 5B). This indicates that py-THQ prefers desorption over hydrogenation, in line with our experimental observation that the selectivity of py-THQ is high at the initial stage of quinoline hydrogenation. Due to the presence of abundant empty sites on pure Ir, py-THQ could readsorb at the surface active sites for further hydrogenation to DHQ. Therefore, the selectivity towards DHQ will increase with prolonged reaction time over Ir catalyst. However, the remarkable selectivity of quinoline hydrogenation towards py-THQ is highlighted on Ir<sub>1</sub>/ $\alpha$ -MoC even under long reaction time. On one hand, the calculated activation barrier for py-THQ further hydrogenation is 0.86 eV which is 0.11 eV higher than py-THQ desorption energy (Figure S16). This demonstrates that the generated py-THQ product will desorb rather than undergo further hydrogenation resulting in a high selectivity of py-THQ on Ir<sub>1</sub>/ $\alpha$ -MoC catalyst. On the other hand, the surface of Ir<sub>1</sub>/ $\alpha$ -MoC tends to be covered with O/OH/H species (Figure S14) via water dissociation, leaving no sufficient empty sites for py-THQ readsorption and further hydrogenation. Quinoline hydrogenation can proceed fast on Ir<sub>1</sub>/ $\alpha$ -MoC due to its stronger adsorption strength and lower hydrogenation reaction barriers as compared with py-THQ. In other words, the selectivity towards DHQ by quinoline hydrogenation on Ir<sub>1</sub>/ $\alpha$ -MoC is significantly low due to the weak adsorption of py-THQ and lack of sufficient empty active site for py-THQ readsorption for further hydrogenation (Scheme 1).

## CONCLUSION

In this work, we demonstrate the construction of an Ir/ $\alpha$ -MoC catalyst with high density of atomically dispersed Ir species (up to 4 %) for hydrogenation reaction of quinoline to py-THQ. XAFS and STEM characterization demonstrate that the 4% Ir/ $\alpha$ -MoC catalyst realizes full atomic dispersion of Ir, whereas the 7% Ir/ $\alpha$ -MoC owns the highest density of isolated Ir<sub>1</sub> atom on  $\alpha$ -MoC with the co-existence of small Ir clusters. The reaction data indicates that high-density isolated Ir atoms are the key factor to acquire remarkable metal-normalized activity and mass-specific activity, whereas  $\alpha$ -MoC host contributes to block the unselective hydrogenation of benzene ring in quinoline at harsh reaction conditions (120 °C, 40 hrs). First-principles microkinetic simulations reveal that

water-mediated hydrogenation mechanism is dominant on Ir/ $\alpha$ -MoC catalysts as opposed to the direct hydrogenation pathway on Ir catalyst. The quinoline hydrogenation activity of Ir/ $\alpha$ -MoC is comparable to that of Ir, due to the low hydrogenation barriers over Ir/ $\alpha$ -MoC in the water-mediated hydrogenation pathway. For Ir/ $\alpha$ -MoC catalysts, the high selectivity of quinoline hydrogenation towards py-THQ originates from the weak adsorption of py-THQ and the lack of sufficient empty active sites for py-THQ readsorption and hydrogenation. The present work not only reports a strategy to construct atomically-dispersed Ir/ $\alpha$ -MoC catalyst with high metal loading and thermal stability, but also provides a new strategy for improving the selectivity of a chemical reaction by selectively switching off some of undesired reaction path using carbide-supported metal catalysts.

## METHODS

$\alpha$ -MoC support was synthesized via a temperature progress annealing of MoO<sub>3</sub>. 0.8 g of MoO<sub>3</sub> powder loaded in quartz tube reactor was placed in a vertical furnace. Then, the powder was heated to 700 °C in NH<sub>3</sub> flow (160 mL min<sup>-1</sup>) at a rate of 5 °C/min and held at 700 °C for 2 hrs. After cooling to room temperature (RT), NH<sub>3</sub> was switched by CH<sub>4</sub>/H<sub>2</sub> mixture (100 mL/min; 20/80 v/v). The temperature was increased to 700 °C (5 °C/min) and kept for 2 hrs. Finally, the sample is cooled to RT and passivated with 0.5% O<sub>2</sub>/Ar gas.

Ir/ $\alpha$ -MoC with different Ir content was synthesized through wet-impregnation method under Ar atmosphere. Taking 7% Ir/ $\alpha$ -MoC as an example, 100 mg of  $\alpha$ -MoC powder and 1 mL of 20 mg/mL IrCl<sub>3</sub> aqueous solution were mixed. After stirring for 2 hrs, water was evaporated and the sample was frozen dried overnight. Then the sample was treated in 20 mL/min of CH<sub>4</sub>/H<sub>2</sub> mixture (15/85 v/v) at 590 °C for 2 hrs. After cooling to RT, the sample was transferred into reaction mixture without exposure to atmosphere for catalytic test.

**Figure 1.** (A) Schematic illustration for the synthesis of atomically dispersed Ir/α-MoC catalyst. (B) XRD patterns of α-MoC and Ir/α-MoC catalysts with different Ir content. (C) Ir L<sub>3</sub> edge XANES spectra of the Ir/α-MoC catalysts; (D) EXAFS spectra of the Ir/α-MoC catalysts and references.

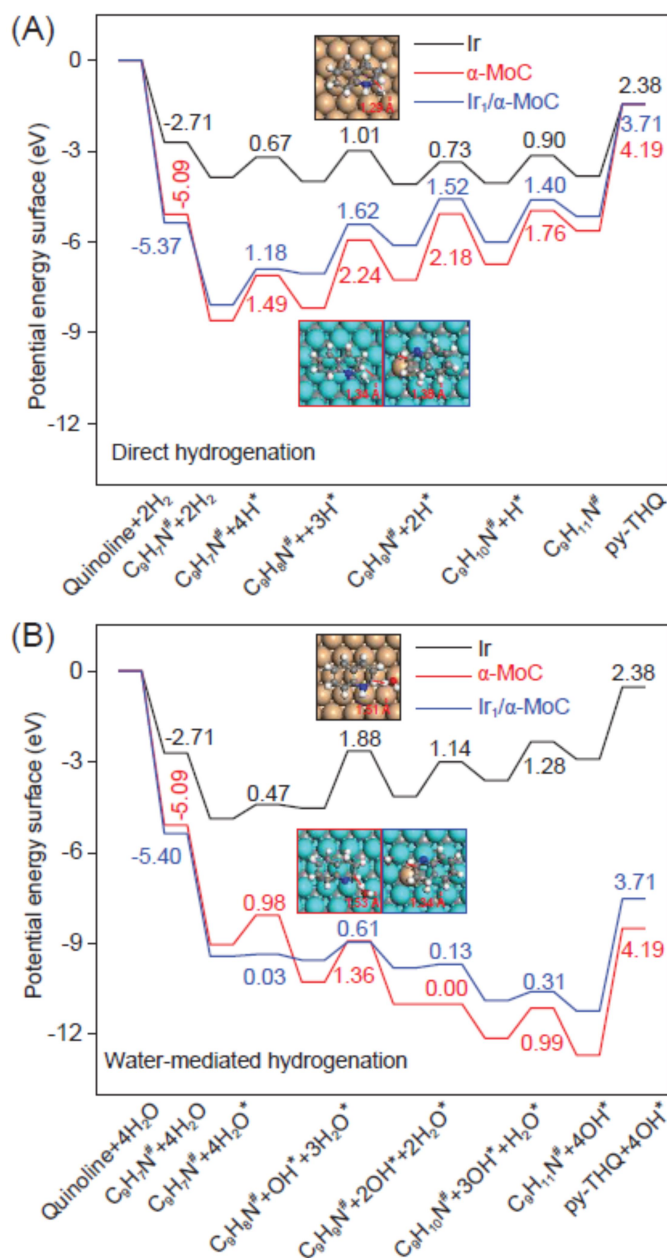

**Figure 2.** (A) A typical STEM-HAADF image of the 4% Ir/α-MoC sample. (B-D) Atomic-resolution STEM-HAADF images of Ir/α-MoC samples with different Ir loading. Atomically dispersed Ir atoms are marked with circles while Ir clusters are indicated by dashed yellow ellipses.

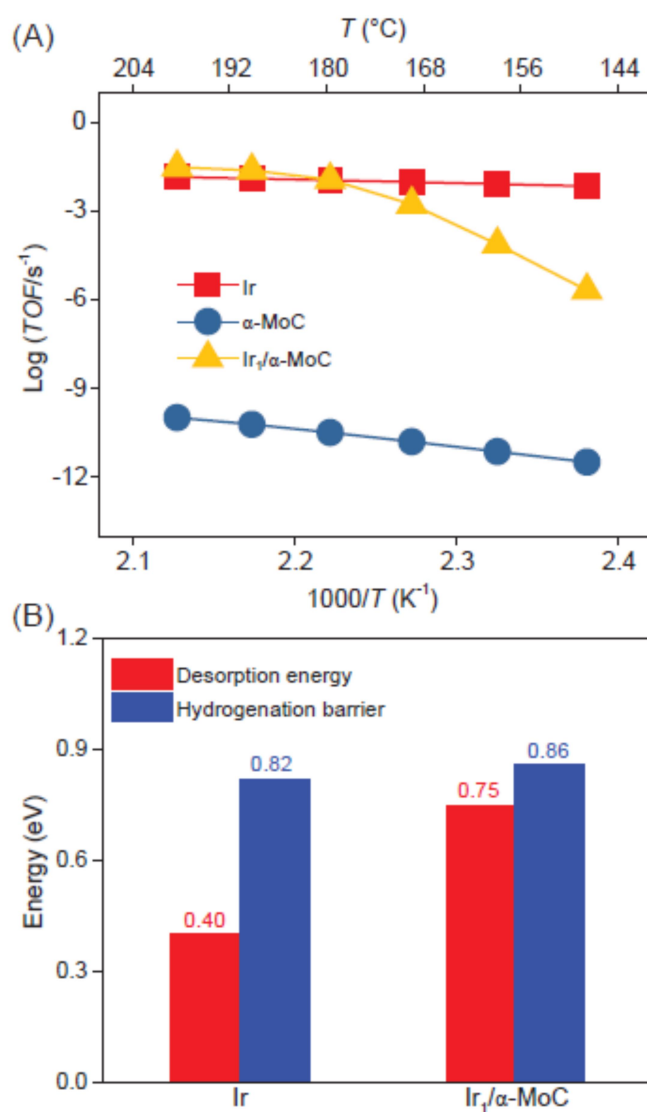

**Figure 3.** (A) Metal-normalized activity and mass-specific activity of Ir/α-MoC catalysts with different Ir content. Ir<sub>1</sub> stands for atomically dispersed Ir. The shade highlights that when Ir loading is lower than 4%, the dominant species are Ir<sub>1</sub>, while it gradually changes the mixture of Ir<sub>1</sub>, Ir clusters and Ir nanoparticles at higher Ir loading. (B) Time dependent selectivity for hydrogenation of quinoline over 7% Ir/α-MoC and 7% Ir/C catalysts. (C) The selectivity of quinoline hydrogenation over Ir/α-MoC and reference Ir-based catalysts at 40 hrs.

**Figure 4.** DFT calculated potential energy diagrams for direct (A) and water-mediated (B) quinoline hydrogenation towards py-THQ over Ir (111),  $\alpha$ -MoC(111) and Ir<sub>1</sub>/ $\alpha$ -MoC(111) surfaces. Quinoline/py-THQ adsorption energies and activation barriers for quinoline hydrogenation are indicated in eV. The transition states configurations for C<sub>9</sub>H<sub>8</sub>N hydrogenation are shown and the corresponding bond length between C and H fragments at transition states are given in Å. The cyan, orange, grey, red, blue and white spheres are Mo, Ir, C, O, N and H atoms, respectively.

**Figure 5.** (A) Predicted reaction rate (TOF, s<sup>-1</sup>) of quinoline hydrogenation towards py-THQ over Ir, α-MoC and Ir<sub>1</sub>/α-MoC surfaces by microkinetic simulations. (B) DFT calculated activation barrier for py-THQ hydrogenation and desorption energy of py-THQ over Ir and Ir<sub>1</sub>/α-MoC surfaces. All energies are indicated in eV unit and py-THQ desorption energy is normalized per site.

**Scheme 1.** The different mechanisms for quinoline hydrogenation over Ir and Ir<sub>1</sub>/α-MoC surfaces. Direct hydrogenation of quinoline is preferable over Ir particles in the formation of DHQ, whereas water-promoted quinoline hydrogenation pathway is more favorable on Ir<sub>1</sub>/α-MoC catalyst with a high selectivity toward py-THQ. The cyan, orange, grey, red, blue and white spheres are Mo, Ir, C, O, N and H atoms, respectively. Transition state is abbreviated as TS.

**Table 1.** The catalytic performance of Ir/ $\alpha$ -MoC and Ir/C in the hydrogenation reaction of quinoline <sup>a</sup>.

Entry	Catalyst	T (°C)	t (hrs)	Conv. (%)	Select. of py-THQ (%)	Select. of DHQ (%)
1	$\alpha$ -MoC	120	1	3	>99	n.d. <sup>b</sup>
2	0.5% Ir/ $\alpha$ -MoC	120	1	16	>99	n.d.
3	4% Ir/ $\alpha$ -MoC	120	1	81	>99	n.d.
4	7% Ir/ $\alpha$ -MoC	120	1	95	>99	n.d.
5	12% Ir/ $\alpha$ -MoC	120	1	77	>99	n.d.
6	7% Ir/C	120	1	97	94	6

<sup>a</sup> Reaction condition: catalyst (30 mg), 40 mg quinoline, 3 mL of CH<sub>3</sub>OH/H<sub>2</sub>O (v:v=1:1) as solvent, 3.0 MPa of H<sub>2</sub>.

<sup>b</sup> Not detected (n.d.) by GC-MS.
